 $[h_0 = 150 \mu m \mid v = 200 \mu m/s]$

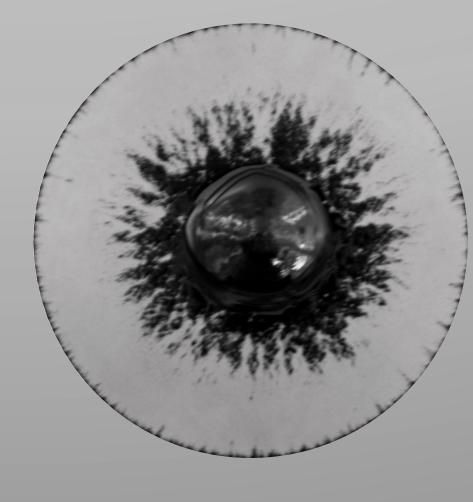

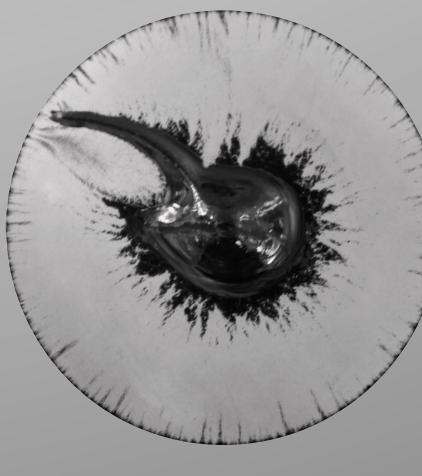

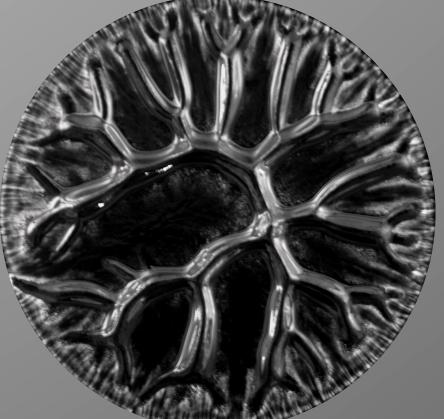

Initial gap width

[4% wt. | $v = 200 \mu m/s$]

Lift velocity

[6% wt. | $h_0 = 100 \mu m$]

A carbon black gel is sandwiched between two parallel plates separated by a gap h_0 . The upper plate is lifted at a constant velocity v. We show the existence of two critical parameters that determine the onset of unstable growth: a minimal lift velocity and a maximal gap width. In the unstable regime, finger-like structures form originating from the classical Saffman-Taylor instability at the gel-air interface. The diameter of the resulting pattern is controlled by the yield strain of the gel. Finally, for small gap width, the finger growth occurs by a stick-slip instability (bottom right image).
